We report the detection and polarization of nuclear spins in diamond at room temperature by using a single nitrogen-vacancy (NV) center. We use Hartmann-Hahn double resonance to coherently enhance the signal from a single nuclear spin while decoupling from the noisy spin-bath, which otherwise limits the detection sensitivity. As a proof-of-principle we: (I) observe coherent oscillations between the NV center and a weakly coupled nuclear spin, (II) demonstrate nuclear bath cooling which prolongs the coherence time of the NV sensor by more than a factor of five. Our results provide a route to nanometer scale magnetic resonance imaging, and novel quantum information processing protocols.

Measurements of nuclear spin moments are essential to numerous fields including medicine [1], chemistry [2], metrology [3], and quantum information processing (QIP) [4]. Within these, detection and manipulation of single or few nuclear spins may revolutionize microscopy of biological systems with the possibility to reveal the structure of single molecules. Moreover, the potential of single nuclear spins as long-lived quantum memory units for this task: its optical polarization and spin-dependent photoluminescence along with long ground-state coherence time, make it a perfect probe for sensing nuclear spins coupled to it via dipole-dipole interaction [10].

As the large background noise originating from the spin-bath makes dynamical decoupling techniques a necessity [11], the optimal way to uncover the target signal is not yet fully clear. Recently, three studies have demonstrated the use of pulsed dynamical decoupling to isolate the signal of a single nuclear spin from the nuclear bath [12, 13]. Other complementary techniques, applied to small ensembles, have observed statistical fluctuations of nuclear spin states [14, 15]. These signals can be greatly enhanced by hyperpolarization of the nuclei, if such is at disposal.

Here we experimentally show that one can use continuous dynamical decoupling (CDD) [17] to overcome both challenges, namely to separate a single nuclear spin signal from the bath noise, and to actively enhance the nuclear polarization of the surrounding bath. In CDD, one applies a continuous, resonant field to isolate the driven spin sensor from its environment. The sensor is then insensitive to the surrounding spins, however specific frequency components can be selected through a phenomenon known in nuclear magnetic resonance as Hartmann-Hahn double resonance (HHDR) [13, 20]. We use this technique to experimentally implement an imaging scheme recently proposed in reference [10], and to study existing limitations. We further demonstrate that CDD can be used (through the spin-locking sequence [2]), to enable direct polarization of the target nuclear systems [21, 22].

HHDR occurs when two spins with distinct energy separation are simultaneously driven so that their oscillation (Rabi) frequencies become resonant, or alternatively, when one species is driven with a Rabi frequency that is equal to the natural energy scale of the other spin [20]. Polarization exchange between the two spin systems can then occur via cross-relaxation, which is usually suppressed by their energy mismatch. In our experiments, corresponding to the latter case, we drive a single NV electronic spin with a Rabi frequency that matches the Zeeman energy of a nearby nuclear spin. This enhances the coherent exchange interaction between the two spins, which would otherwise be prohibited due to the three orders of magnitude energy difference (Fig. 1a,b). By adjusting the intensity of the driving field, the NV spin sensor can be used as a tunable, narrow-band spectrometer [20], with spectral resolution limited only by the decoupling efficiency and interrogation time.

Hartmann-Hahn dynamics with a single NV-center. The interaction of the NV electronic spin, S, with an additional $^{13}C$ nuclear spin, I, can be described by the dipole-dipole term $H_{NV-^{13}C} = S_z \cdot \mathbf{A}_{hyp} \cdot I$, where $\mathbf{A}_{hyp}$ is the hyperfine vector (defined in [14, 22]), and non-
secular terms are neglected due to the energy mismatch of the two spins \( \text{[24]} \). We consider a continuous driving field \( \Omega \). The NV center can be described in the MW-dressed basis by \( \gamma \). At HHDR, its energy scale equals to the nuclear spin scale and coherent oscillations between the \(+, \downarrow\) level and the \(-, \uparrow\) level (green curve) are enhanced.

\[
\Omega = \gamma_N |B_{eff}| = \gamma_N |B - (1/2)A_{hyp}|, \quad (1)
\]

can be engineered. Then, the energy scale of the dressed NV center, \( \Omega \), matches the local energy scale of the nuclear spin, \( \gamma_N |B_{eff}| \), where \( \gamma_N \) is the gyromagnetic ratio, and \( B_{eff} \) is the effective local magnetic field at the nuclear spin position (\( B \) is the external magnetic field). At the resonance, specifically if the difference between their energy scales becomes smaller than their mutual coupling strength, the electron-nuclear interaction dominates the dynamics and coherent oscillations between the \(|\pm\rangle\) dressed-states and the \(|\uparrow, \downarrow\rangle\) nuclear states (where \( \downarrow \) is defined along the direction of \( B_{eff} \) (Fig. 1c)) may occur. The probability of finding the dressed NV center, initially set to the state \(|+\rangle\), in the opposite state \(|-\rangle\), after time \( \tau \), is

\[
p(\tau, \Omega) = \frac{J^2}{J^2 + (\Omega - \gamma_N |B_{eff}|)^2} \times \\
\sin^2 \left( \frac{J^2 + (\Omega - \gamma_N |B_{eff}|)^2 \tau^2}{2} \right), \quad (2)
\]

where \( J \), given by

\[
J = \frac{1}{4} \gamma_N |A_{hyp}| \sin \theta, \quad (3)
\]

is proportional to the coupling strength, and depends on \( \theta \), the angle between \( B_{eff} \) and \( A_{hyp} \) (See \( \text{[24]} \)). The transition probability (Eq. (2)) shows temporal oscillatory behavior, and a spectral dependence (Lorentzian shape of width \( J \)). The former is a manifestation of the coherent nature of this interaction; Starting in the \(+, \downarrow\) state, the system evolves according to \(|\Psi\rangle = |+\downarrow\rangle \cos (Jt) + |-\uparrow\rangle \sin (Jt)\). Thus, at time \( t = \pi/2J \) the two spins become maximally entangled, and after a \( t = \pi/J \) a full population transfer occurs; i.e. the states of the two spins are swapped. The latter, i.e. the spectral dependence in Eq. (2) reflects that coherent oscillations between the NV center and weakly coupled nuclear spins are extremely sensitive to detuning from the Hartmann-Hahn condition.

**Single nuclear spin spectroscopy and imaging.** In our experiments, HHDR is performed with single NV cen-

![Figure 1](image1.png)

**Figure 1:** (color online) (a) Ground-state energy level structure of the NV center as a function of an axial magnetic field. At a magnetic field of 0.54 T, the NV center ground states \( m_s = 0, -1 \) have an energy separation of 12 GHz, and the nuclear system is split by 6 MHz (Red box). (b) Energy-level diagram of the NV center electronic ground-state and a single \(^{13}\)C nuclear spin. The coupling term, \( A_{hyp} \), induces flip-flops between the electron spin and a coupled nuclear spin (green arrow), which are suppressed by the mismatch of the electronic and nuclear energies (blue and red arrows, respectively). (c) The energy level diagram in the presence of a resonant MW field. The electronic spin is described by the dressed basis \(|\pm\rangle\). At HHDR, its energy scale equals to the nuclear spin scale and coherent oscillations between the \(|+\uparrow\rangle\) level and the \(|-\downarrow\rangle\) level (green curve) are enhanced.
ters in a natural abundance (\(^{13}\text{C} \, 1.11\%\)) diamond. Details on the diamond sample, and on the experimental setup and procedure can be found in the supplementary material \([22]\). In order to increase the decoupling efficiency, we apply a high Rabi frequency of \(\sim 6\, \text{MHz}\) which is matched by the Larmor frequency of the \(^{13}\text{C}\) nuclear spins in a magnetic field of 0.54 T (Fig. 1a). The transition probability in Eq. (2) can be measured in a straightforward way by applying a spin-locking sequence (Fig. 2a) \([20, 21]\). As will be described later, this protocol produces polarization of the nuclear bath, inhibiting further interaction between the NV center and nearby nuclear spins. Therefore, for spectroscopy measurements, i.e., characterization of the coupling strength and orientation, an alternating version of the spin-locking sequence was used (Fig. 2b), which produces the same experimental signal but without polarization of the nuclear bath. It comprises two similar sequences \(\text{"+"}\) and \(\text{"-"}\), which induce nuclear polarization in alternating directions, thus the net nuclear polarization is zero.

Fig. 2c shows the measurement of the transition probability for a single NV center interacting with the surrounding spin-bath. Two features which correspond to interaction with nuclear spins can be seen at \(\Omega \approx 5.75\, \text{MHz}\) and at \(\Omega \approx 5.9\, \text{MHz}\). The first agrees well with the expected Larmor frequency for \(^{13}\text{C}\) spins in the applied field (\(|B| = 5375\, \text{G}\)), and shows loss of coherence of the \(|\pm\rangle\) state due to the interaction with many nuclear spins. The second feature is the realization of HHDR with a single nuclear spin, whose coupling strength with the NV center (\(\sim 200\, \text{kHz}\)) is 2.5 times smaller than the measured inhomogeneous \((T_2^*)\) linewidth, which characterizes the phase-detection sensitivity without decoupling. Since for our experimental parameters HHDR is efficient for only one hyperfine projection of the nitrogen nuclear spin of the NV-center (a spin half, \(^{15}\text{N}\) nucleus in this case), the high oscillation contrast of 40\% indicates an almost complete polarization exchange with the single \(^{13}\text{C}\) spin. The two-dimensional nature of Eq. (2), i.e., the spectral and temporal dependencies, also allows for nuclear spin imaging (Fig. 2d): Both the optimal Rabi frequency \(\Omega_{\text{opt}}\) which satisfies Eq. (1), and the oscillation rate at double-resonance (Eq. (3)) contain information about the interaction strength, \(|A_{\text{hyp}}|\) and its orientation, \(\theta\). Inverting Eq. (1) and Eq. (3) for this electron-nuclear pair (\(\Omega_{\text{opt}} = 2\pi \times (5.88 \pm 0.03)\, \text{MHz},\) \((J = 2\pi \times (188 \pm 30)\, \text{kHz})\)), we deduce that the coupling for this pair is \((1/4)\gamma_N|A_{\text{hyp}}| = 2\pi \times 220 \pm 40\, \text{kHz}\) (which corresponds to a nuclear spin located \(\sim 0.5\, \text{nm}\) from the NV center, assuming the contribution from the contact term in the interaction is negligible), and the orientation is \(\theta = 56 \pm 10^\circ\).

The measured coupling, \(\sim 200\, \text{kHz}\), does not mark the ultimate sensitivity of our scheme. Coherent oscillations of the NV-nuclear pair last for more than 25 \(\mu\)s, implying that a 40 kHz coupling could have been detected if such a nuclear spin was present in the vicinity of this NV center. In principle, the interrogation time and hence the sensitivity of the HHDR scheme, is limited by \(T_1^*\) - the longitudinal relaxation time of the NV center in the rotating frame \([2]\). \(T_1^*\) times exceeding one millisecond have been measured for NV centers at room temperature \([22]\), which translates to sub-kHz resolution. However both practical and fundamental aspects limit the sensitivity of the scheme. First, fluctuations in the applied MW and static magnetic fields cause broadening and reduce the achieved interrogation time. This may be overcome with improved concatenated continuous driving schemes which mitigate the impact of MW instabilities \([27]\). Second, the decoupling efficiency of CDD depends on the spectral overlap of the noise spectral density with the decoupling filter function \([11]\). The overlap may be reduced by modifying either the filter function or the bath spectrum to achieve optimal decoupling performance. For example, to target detection of protons \([13, 16]\), the NV-center can be tuned to the proton spectral region, which is detuned from \(^{13}\text{C}\) nuclear spins in moderate magnetic fields. However, in our experiment we aimed to separate the signal of individual \(^{13}\text{C}\) nuclear spins from a bath comprised from the same nuclear species. Then the spectral density of the bath is peaked near the interrogated frequencies (shifted by only the coupling interaction between the sensor and target spin) leading to a reduced \(T_1^*\) coherence time \([28]\).

For a detailed discussion on the sensitivity of the scheme, see \([20, 30]\) and \([22]\).

**Nuclear spin-bath polarization.** In addition to the detection of single or few nuclear spins, one can utilize the direct flip-flops between the NV center and nuclear spins to polarize the surrounding bath (Figure 3). Under HHDR, the \(|\text{+}, \text{↓}\rangle \leftrightarrow |\text{−}, \text{↑}\rangle\) transition allows transfer of polarization from the NV electronic spin to resonant nuclear spins. Therefore, when optical polarization of the NV spin is established at the beginning of each sweep an efficient cooling mechanism of the nuclear spin-bath is provided. We note that other transitions between the dressed-electronic spin and the nuclear spin can lead to a reversal of polarization \([23]\). However these transitions are suppressed by an energy mismatch described by \(\sim (J/\Omega)^2\), and in our high-field experiments are of the order \(1 \times 10^{-3}\). We observe the bath polarization experimentally in the spin-locking signal when employing the non-alternating sequence (Fig. 2a), which shows no oscillations as the system is driven into a non-interacting state in which all the nuclear spins are polarized to their up state \([22]\). The bath polarization itself can also be directly observed from an extension of the free induction decay (FID) signal of the NV center, measured using a Ramsey sequence.

The results show that when the bath is polarized the NV phase memory time, \(T_2^*\), increases five-fold in comparison with a non-polarized bath (Fig. 3a). Further improvements in \(T_2^*\) are limited by magnet drifts of our setup. Since the polarization process now carries a statistical nature, due to the probability of flipping the state of the nearby spins, we can investigate its characteristics. First, we demonstrate a precise control on the degree of polarization by biasing the rates of polariza-
fundamental processes such as inter-nuclear interactions.

nuclear-bath polarization as demonstrated here, provides induced polarization [33]. Initializing and probing the interest to discriminate this process from spin-diffusion resolved in our measurement, but it would be of great duration of nearby nuclear spin positions. Polarization for different NV centers due to variations in the configuration is achievable (Fig. 3b). Finally, we measure the dynamics of the bath polarization by varying the number of polarization sweeps and measure the FID signal (Fig. 3c). [31] The experimental results are in qualitative agreement with a numerical simulation of a master equation for a single NV center surrounded by 500 13C spins [32]. The simulation indicates that this scheme polarizes close lying nuclear spins very efficiently (almost one spin per sweep). These spins have the greatest influence on the FID linewidth, but their effect can vary for different NV centers due to variations in the configuration of nearby nuclear spin positions. Polarization of spins which are farther away is much slower and unresolved in our measurement, but it would be of great interest to discriminate this process from spin-diffusion induced polarization [33]. Initializing and probing the nuclear-bath polarization as demonstrated here, provides an experimental route for characterizing and measuring fundamental processes such as inter-nuclear interactions.

Conclusions. We have shown that using continuous dynamical decoupling, a single NV-center can sense minute magnetic fields originating from a single nuclear spin, in spite of the large background noise produced by its environment. We have also demonstrated that a careful tuning of the protocol may bring forth room-temperature hyperpolarization among nuclei in the surrounding bath. The interaction between the NV electronic spin and the nuclear spins preserves its coherent nature, i.e. it can support quantum information protocols using dressed qubits [34].

In biological measurements which are characterized with an extremely disruptive environment, CDD can become an optimal tool: First, it allows improved decoupling through high Rabi frequencies and high magnetic field with efficient energy expenditure compare to pulsed techniques, and would thus be less invasive to biological samples. In our experiments Rabi frequencies of few MHz were introduced, but Rabi frequencies of hundreds of MHz have been demonstrated using on-diamond MW-waveguides [35]. Second, the target spin signal can be amplified using room-temperature nuclear polarization which improves the signal-to-noise ratio according to $\sqrt{N}$ where $N$ is the number of nuclear spins. Moreover, for many diamond-based QIP protocols, initialization of the nuclear bath to a given state is essential, for example in quantum simulators [36]. We also note that Hartmann-Hahn double resonance can be applied for the detection of electron spins as was demonstrated recently [37].

The authors thank Rainer Pfeiffer and Kay Jahnke for assistance with the experiments. The authors are grateful to Philip Hemmer, Jörg Wrachtrup, Vyacheslav Dobrovitskii and Philipp Neumann for fruitful discussions. The research was supported by DFG (FOR1482, SPP1601 and SFB TR21), EU (DIAMANT), DARPA (QUASAR) and the Alexander von Humboldt Foundation. J.-M.C acknowledges the support of Marie-Curie fellowship and FP7.

[23] Supplementary information.
[24] The energy mismatch can result from the NV-center’s zero-field splitting at zero magnetic field, or from the presence of an external magnetic field $B$ (provide that the NV’s is not at the level anti-crossing).
[31] To initialize (depolarize) the nuclear bath before each measurement, we have used many sweeps of the alternating sequence.
